E ciency and Foreclosure E ects of Vertical Rebates: Empirical Evidence

Christopher T. Conlon^y Julie Holland Mortimer^z

June 7, 2017

Abstract

Vertical rebates are prominently used across a wide range of industries. These contracts may induce greater retail e ort, but may also prompt retailers to drop competing products. We study these o setting e ciency and foreclosure e ects empirically, using data from one retailer. Using a eld experiment, we show how the rebate allocates the cost of e ort between manufacturer and retailer. We estimate models of consumer choice and retailer behavior to quantify the rebate's e ect on assortment and retailer e ort. We nd that the rebate increases industry pro tability and consumer utility, but fails to maximize social surplus and leads to upstream foreclosure.

We thank Mark Stein, Bill Hannon, and the drivers at Mark Vend Company for implementing the experiment used in this paper, providing data, and generally educating us about the vending industry. We thank Susanto Basu, Michaela Draganska, Scott Hemphill, Wills Hickman, J. F. Houde, Sylvia Hristakeva, Robin Lee, Joe Quinn, Michael Riordan, Greg Sha er, Mike Whinston, and seminar participants at Bates White, Boston College, Boston University, Harvard Business School, Harvard University (Economics Department), MIT, Pennsylvania State University, Rochester University, SUNY Stony Brook, Texas A & M University, Toulouse School of Economics, Tufts University, Universitat Autonoma de Barcelona, Universitat Pompeu Fabra, University of Toronto, University of Virginia, Washington University in St. Louis, Yale University, and participants at the Quantitative Marketing and Economics conference and the Workshop on Conditional Pricing Practices (held jointly by the Department of Justice and the Federal Trade Commission), for helpful comments. Any remaining errors are our own.

1 Introduction

Vertical arrangements between manufacturers and retailers have important implications for how markets function. These arrangements may align retailers' incentives with those of manufacturers, and induce retailers to provide demand-enhancing e ort. However, they may also reduce competition, exclude competitors, and limit product choice for consumers. Many types of vertical arrangements can induce these o setting e ciency and foreclosure e ects, including resale price maintenance, exclusive dealing, vertical bundling, and rebates, among other contractual forms. Accordingly, these arrangements are a primary focus of antitrust authorities in many countries. Vertical rebates in particular are prominently used across a wide range of industries, including pharmaceuticals, hospital services, microprocessors, snack foods, and heavy industry, and have been the focus of several recent Supreme Court cases and antitrust settlements.¹

Although vertical rebate contracts are important in the economy and have the potential to induce both pro- and anti-competitive e ects, understanding their economic impacts can be challenging. Tension between the potential for e ciency gains on one hand, and exclusion of upstream rivals on the other hand, implies that the contracts must be studied empirically in order to gain insight into the relative importance of the two e ects. Unfortunately, the existence and terms of these contracts are usually considered to be proprietary information by their participating rms, frustrating most e orts to study them empirically. An additional challenge for analyzing the e ect of vertical contracts is the diculty in measuring downstream e ort, both for the upstream rm and the researcher.

We address these challenges by examining a vertical rebate known as an All-Units Discount (AUD). The speci c AUD we study is used by the dominant chocolate candy manufacturer in the United States: Mars, Inc.² The AUD implemented by Mars consists of three main features: a retailer-speci c per-unit discount, a retailer-speci c quantity target or threshold, and a 'facing' requirement that the retailer carry at least six Mars products.

¹Di erent forms of vertical rebates include volume-based discounts and `loyalty contracts.' Volume-based discounts tie payments to a retailer's total purchases from the rebating manufacturer, but do not reference the sales of competing manufacturers. An all-units discount is a particular type of volume-based discount in which the discount is activated once sales exceed a volume threshold. Once activated, the discount applies retroactively to all units sold. We use the term `loyalty contracts' to refer to payments that are calculated based on a retailer's sales volumes of both the rebating, and competing, manufacturers. Genchev and Mortimer (forthcoming) provides a review of empirical evidence on this class of contracts, including many of the relevant court cases.

²With revenues in excess of \$50 billion, Mars is the third-largest privately-held company in the United States (after Cargill and Koch Industries).

Mars' AUD stipulates that if a retailer meets the facing requirement and his total purchases exceed the quantity target, Mars pays the retailer an amount that is equal to the per-unit discount multiplied by the retailer's total quantity purchased. We examine the e ect of the rebate contract through the lens of a retail vending operator, Mark Vend Company, for whom we are able to collect extremely detailed information on sales, wholesale costs, and contractual terms. The retailer also agreed to run a large-scale eld experiment on our behalf, in which we exogenously remove two of Mars' best-selling products and observe subsequent substitution patterns, as well as the pro t/revenue impacts for the retailer and all manufacturers. This provides important insight into the e ect of the retailer's actions on manufacturer revenues, as well as the potential impact of the AUD on the retailer's decisions. To the best of our knowledge, no previous study has had the bene t of examining a vertical rebate contract using such rich data and exogenous variation.

The insights that we gain from studying Mars' rebate contract allow us to contribute to understanding principal-agent models in which downstream moral hazard plays an important role. Downstream moral hazard arises whenever a downstream rm takes a costly action that is bene cial to the upstream rm but not fully contractible. It is an important feature of many vertically-separated markets, and is thought to drive a variety of vertical arrangements such as franchising and resale price maintenance (RPM).³ However, empirically measuring the e ects of downstream moral hazard is di cult. Downstream e ort may be impossible to measure directly, and vertical arrangements are endogenously determined, making it difcult to identify the e ects of downstream moral hazard on upstream rms. Our ability to exogenously vary the result of downstream e ort (in this case, retail product availability), combined with detailed data on wholesale prices, allows us to directly document the e ects of downstream moral hazard on the revenues of upstream rms.

In order to analyze the e ect of Mars' AUD contract, we specify a model of consumer

of vertical restraints goes back at least to Telser (1960) and the *Downstream Moral Hazard* problem discussed in Chapter 4 of Tirole (1988).⁸ An important theoretical development on the potential foreclosure e ects of vertical contracts is the so-called *Chicago Critique* of Bork (1978) and Posner (1976), which makes the point that because the downstream rm must be compensated for any exclusive arrangement, one should only observe exclusion in cases for which it maximizes the pro ts of the entire industry. Subsequent theoretical literature

on downstream moral hazard or e ort decisions.¹⁵ The most closely-related empirical work is work on vertical bundling in the movie industry, and on vertical integration in the cable television industry. The case of vertical bundling, known as full-line forcing, is studied by Ho, Ho, and Mortimer (2012a) and Ho, Ho, and Mortimer (2012b), which examine the decisions of upstream rms to o er bundles to downstream retailers, the decisions of retailers to accept these 'full-line forces,' and the welfare e ects induced by the accepted contracts. The case of vertical integration is studied by Crawford, Lee, Whinston, and Yurukoglu (2015), which examines e ciency and -469(and)-4Dsy cy15 ac15to15

and when substitute products or alternative distributors are not widely available." While the wide variety of arrangements and the diversity of market structures makes generalization di cult with any observed CPP (including the one we study here), the potential for both anti-competitive and e ciency e ects makes it important to build on the empirical body of knowledge about these arrangements. As Genchev and Mortimer (forthcoming) point out, it is especially important to empirically analyze the impacts of CPPs that have not been selected through a process of litigation, to avoid selection bias in the set of contracts examined in the literature.

The rest of the paper proceeds as follows. Section 2 provides the theoretical framework for the model of retail behavior. Section 3 describes the vending industry, data, and the design and results of the eld experiment, and section 4 provides the details for the empirical implementation of the model. Section 5 provides results, and section 6 concludes.

2 Theoretical Framework

2.1 Foreclosure and Optimal Assortments: A Motivating Example

We begin by providing a working de nition, as well as some examples of the measures of foreclosure and optimal assortment to be used throughout the rest of our paper. To begin, we focus exclusively on the assortment decision (ignoring e ort provision) of the downstream retailer (R) in response to a contract o ered by a dominant upstream rm (M)

(H;H). The dominant rm M o ers the retailer R a transfer T in exchange for switching from (H;H) ! (M;M). In order to make the retailer's decision non-trivial, we assume that R(M;M) < R(H;H) (i.e., the retailer earns higher pro ts when stocking the rival's products). The following conditions (A1)-(A3) ensure that such a transfer is sulcient for M to foreclose its rival H.

(A1)
$$R + T = 0$$

(A2)
M
 T 0

(A3) -
$$H M + R$$

(A1) speci es that the retailer prefers to switch from (H;H) ! (M;M) after receiving a transfer of size T; (A2), that the dominant rm would be wiling to pay T to induce the retailers to switch from (H;H) ! (M;M). The third assumption (A3) says that the protts lost by the rival H are smaller than those gained by M and R combined. Thus, (A3) guarantees that even if H o ered its own transfer equal to its entire lost prots H(H;H), it could not prevent foreclosure. H(H;H)

The ability to obtain foreclosure as an equilibrium outcome is guaranteed by (A3), which may also be restated as I R H H H H H H H G G

Adding a Third Assortment

Now we introduce a new assortment (H;M) which yields intermediate pro ts for all players:

$${}^{R}(H;H) > {}^{R}(H;M) > {}^{R}(M;M)$$

$${}^{H}(H;H) > {}^{H}(H;M) > {}^{H}(M;M)$$

$${}^{M}(H;H) < {}^{M}(H;M) < {}^{M}(M;M)$$

$$(1)$$

¹⁹Under an AUD, the transfer would be conditional on meeting a quantity threshold or a facing requirement that is only satis ed under an (M;M) assortment.

²⁰If H is fully excluded from the retailer shelf then H(M;M) = 0 and H = H(H;H).

²¹The e ect of the change in assortment on consumer surplus $^{C} > 0$ or overall social surplus, $^{C} +$ may di er from its e ect for the industry.

For this case, we ignore the possibility of (M;M), and introduce a new operator H = (H;M) (H;H), with the same set of assumptions:

(B1)
$$_{H}$$
 R + T_{h} 0

(B2)
$$_{H}$$
 M T_{h} 0

Proofs in Appendix A.1.

The main takeaway is that M can set the vector of transfer payments T; T_h ; and T_m in order to obtain full (M;M) or partial (H;M) foreclosure. We show that under (A1)-(A3), full foreclosure is feasible.²² However, if (B1)-(B3) and (C1), (C2), and (C4) also hold, full foreclosure does not lead to the assortment that maximizes overall industry surplus. In this case, partial foreclosure maximizes industry surplus, but full foreclosure leads to higher bilateral surplus among the retailer and dominant rm. As long as the dominant rm chooses the vector of transfers T, T_h and T_m , full foreclosure will be the equilibrium outcome.

The intuition behind this result relates to that of the *Chicago Critique* of Bork (1978) and Posner (1976), which we interpret as asking \When foreclosure is obtained in equilibrium, must the assortment necessarily be optimal?" Our answer is related to the work by Whinston (1990) on tying. When the dominant \mbox{rm} is able to condition the transfer payment on the (M;M) outcome, he can commit to tying the products together, and thus the equilibrium assortment need not maximize the surplus of the entire industry.

2.2 All Units Discount Rebates

In an All Units Discount (AUD) rebate, the transfer T to the retailer is calculated on the basis of all units sold to the retailer, conditional on obtaining a level of sales at or above a required threshold.

Assuming that the dominant manufacturer o ers the same wholesale price across all

tion of M's pro ts, rather than quantity purchased. Speci cally,

8
$$< R(a) + d q_m(a) \text{ if } q_m(a) \overline{q_m}$$

:
$$R(a)$$
 if $q_m(a) < \overline{q_m}$

cost of providing e ort c(e) is increasing in e. If we hold assortment xed, the retailer's payo s under the AUD, as a function of e ort, are:

8
$$< R(e) C(e) + M(e) if M(e) M$$
 $: R(e) C(e) if M(e) M$

$$(2)$$

The upstream rm can induce greater retailer e ort via both features of the contract: (1) a larger per unit discount increases so that R gives greater consideration to the pro ts of M; (2) a larger choice of $\overline{}^{M}$ leads to greater retailer e ort because $\overline{}^{M}$ (e) is increasing in e ort. In our empirical example, we quantify both of these channels.

We provide a detailed solution to the e ort problem in Appendix A.3. To summarize, when e ort is non-contractible, R chooses one of three solutions to equation (2): either the interior solution to the e ort problem with the rebate (the rst line), which we denote e^R , the interior solution to the e ort problem absent the rebate (the second line), which we denote e^{NR} , or the solution that makes the constraint bind, \bar{e} : \bar{M} (\bar{e}) = \bar{M} . Thus, for \bar{e} = e^R , M can set the e ort level of the retailer via the threshold \bar{M} , subject to satisfying the retailer's IR constraint. The set of e ort levels that the threshold can target potentially includes the vertically-integrated, and the socially-optimal e ort levels. Later, we characterize the critical values of in our empirical exercise.

An important consideration is whether the potential e ciency gains from increased retailer e ort can o set the potential surplus lost from foreclosure. In order to analyze this question, we focus primarily on e ort levels that maximize e ciency gains. One can examine the e ort choice that is optimal for the bilateral/vertically-integrated rm M+R, which we denote e^{VI} , or for the industry (i.e., including pro ts of the rival), which we denote e^{IND} , or the e ort level that maximizes social surplus, denote e^{SOC} .

We enumerate these possibilities below:

$$e^{NR} = arg \max_{e} {R(e) \quad c(e)}$$
 $e^{R} = arg \max_{e} {R(e) \quad c(e)} + {M(e)}$
 $e^{VI} = arg \max_{e} {R(e) \quad c(e)} + {M(e)}$, (3)

n to the e ort problem absent the rebate (the second line), -27(cial)-327(surplus,)-326(denote2)]T07F18 11.9552

 $^{M}(e)$ is increasing everywhere. This can be accomplished by choosing a threshold $^{\overline{M}} > ^{M}(e^{VI})$. For $e < e^{VI}$ the bilateral surplus is increasing in e ort, and for $e > e^{VI}$ the bilateral surplus is decreasing in e ort; however, at all levels of e, e ort (weakly) functions as a transfer from R to M. Thus, in equilibrium, it may be possible to design a transfer that results in socially ine cient excess e ort.

3 The Vending Industry and Experimental Data

3.1 Data Description and Product Assortment

We observe data on the quantity and price of all products sold by one retailer, Mark Vend Company. Mark Vend is located in a northern suburb of Chicago, and services 728 snack machines throughout the greater Chicago metropolitan area.²⁷ Data are recorded internally at each of Mark Vend's machines, and include total vends and revenues since the last service visit to the machine. Any given snack machine can carry roughly 31 standard products at one time. These include salty snacks, cookies, and other products, in addition to 6-8 confection products.²⁸ We observe retail and wholesale prices for each product at each service visit during a 38-month panel for all snack machines in Mark Vend's enterprise. The dataset covers the period from January, 2006 through February, 2009. There is relatively little price variation over time for any given machine, and almost no price variation within a product category (e.g., confections) for a machine.

A focus in our empirical exercise is the set of products the retailer stocks in the last two slots in the confections category. Mark Vend chooses between stocking two additional Mars products (Milkyway and 3 Musketeers) or two Hershey Products (Reese's Peanut Butter Cups and Payday), or one product from each manufacturer. In table 1 we report the national

(around 52% of all confections sales). The non-Mars product most frequently stocked by Mark Vend is Nestle's Raisinets (at 47% of machine-weeks), which does not rank in the top 45 products nationally in confections sales.

There are two possible explanations for Mark Vend's departures from the national best-sellers. One is that Mark Vend has better information on the tastes of its speciec consumers, and its product mix is geared towards those tastes. The alternative explanation is that the rebate induces Mark Vend to substitute from Nestle/Hershey brands to Mars brands when making stocking decisions, and that when Mark Vend does stock products from competing manufacturers (e.g., Nestle Raisinets), he chooses products that do not steal business from key Mars products.

3.2 Mars' AUD with Mark Vend

Mars' AUD rebate program is the most commonly-used vertical arrangement in the vending industry.²⁹ Under the program, Mars refunds a portion of a vending operator's wholesale cost at the end of a scal quarter if the vending operator meets a quarterly sales goal. The sales goal for an operator is typically set on the basis of its combined sales of Mars' products, rather than for individual Mars products. Mars' rebate contract also stipulates a minimum number of product 'facings' that must be present in an operator's machines, although in practice, this provision is di cult to enforce because Mars cannot observe the assortments in individual vending machines. The amount of the rebate and the precise threshold of the sales goal are species to an individual vending operator, and these terms are closely guarded by participants in the industry.

We include some promotional materials from Mars' rebate program in gure 1.³⁰ The program employs the slogan *The Only Candy You Need to Stock in Your Machine!*, and speci es a facing requirement of six products and a quarterly sales target. The second page of the document shown in gure 1 refers to discontinuing a growth requirement, which we

²⁹For confections products, Mars is the dominant manufacturer in vending, and is the only manufacturer to o er a true AUD contract. The AUD is the only program o ered to vendors by Mars. Hershey and Nestle o er wholesale `discounts,' but these have a quantity threshold of zero (i.e., their wholesale pricing is equivalent to linear pricing). The salty snack category is dominated by Frito-Lay (a division of PepsiCo) which does not o er a rebate contract. We do not examine beverage sales, because many beverage machines at the locations we observe are serviced directly by Coke or Pepsi.

³⁰A full slide deck, titled `2010 Vend Program,' and dated December 21, 2009, is available at http://vistar.com/KansasCity/Documents/Mars%202010%20Operatopr%20rebate%20program.pdf. (Last accessed on April 19, 2015; available from the authors upon request.) These promotional materials represent the same type of rebate in which Mark Vend participated, but may di er from the terms available to Mark Vend during the period we study.

believe to be 5% (i.e., a target of 105% of year-over-year sales). On another page, not shown

from around 6.6 to around 5.3. Over the same time period, the number of Hershey facings increased from around 1 facing per machine to around 2 facings per machine. The right-hand-side panel of the table shows that the major switch was to swap Mars' Three Musketeers (stocked in around half of machines at the beginning of the sample) for Hershey's Reese's Peanut Butter Cups and Payday (stocked in 62% and 23% of machines respectively at the end of the sample period). Although it is di-cult to attribute causality, it is worth pointing out that prior to the reduction in the threshold, both Reese's Peanut Butter Cups and Payday are e-ectively foreclosed, as they are stocked in very few of Mark Vend's machines.

product removals are recorded during each service visit.³⁴ Implementation of each product removal was fairly straightforward; the driver removed either one or both of the two top-selling Mars products from all machines for a period of roughly 2.5 to 3 weeks. The focal products were Snickers and Peanut M&Ms.³⁵ The dates of the product removal interventions range from June 2007 to September 2008, with all removals run during the months of May - October. Over all sites and months, we observe 185 unique products. We consolidate products that had very low levels of sales with similar products within a category that are produced by the same manufacturer, until we are left with the 73 `products' that form the basis of the rest of our exercise.³⁶

During each 2-3 week product removal period, most machines receive about three service visits. However, the length of service visits varies across machines, with some machines visited more frequently than others. Machines are serviced on di erent schedules, and as a result, it is convenient to organize observations by machine-week, rather than by visit, when analyzing the results of the experiment. When we do this, we assume that sales are distributed uniformly among the business days in a service interval, and assign those business days to weeks. Di erent experimental treatments start on di erent days of the week, and we allow our de nition of when weeks start and end to depend on the client site

³⁴The machines are located in o ce buildings, and have substitution patterns that are very stable over time. In addition to the three treatments described here, we also ran ve other treatment arms, for salty-snack and cookie products, which are described in Conlon and Mortimer (2010) and Conlon and Mortimer (2013b). The reader may refer to our other papers for more details.

³⁵Whenever a product was experimentally stocked-out, poster-card announcements were placed at the front of the empty product column. The announcements read \This product is temporarily unavailable. We apologize for any inconvenience." The purpose of the card was two-fold: rst, we wanted to avoid dynamic e ects on sales as much as possible, and second, Mark Vend wanted to minimize the number of phone calls received in response to the stock-out events. `Natural,' or non-experimental, stock-outs are extremely rare for our set of machines. This implies that much of the variation in product assortment comes either from product rotations, or our own exogenous product removals. Product rotations primarily a ect `marginal' products, so in the absence of exogenous variation in availability, the substitution patterns between marginal products is often much better identi ed that substitution patterns between continually-stocked best-selling products. Conlon and Mortimer (2010) provides evidence on the role of the experimental variation for identi cation of substitution patterns.

³⁶For example, we combine Milky Way Midnight with Milky Way, and Ru es Original with Ru es Sour Cream and Cheddar. In addition to the data from Mark Vend, we also collect data on product characteristics online and through industry trade sources. For each product, we note its manufacturer,

and experiment.37

Two features of consumer choice are important for determining the welfare implications of the AUD contract. These are, rst, the degree to which Mark Vend's consumers prefer the marginal Mars products (Milky Way, Three Musketeers, Plain M&Ms) to the marginal Hershey products (Reese's Peanut Butter Cup, Payday), and second, the degree to which any of these products compete with the dominant Mars products (Peanut M&Ms, Snickers, and Twix). Our experiment mimics the impact of a reduction in retailer e ort (i.e., restocking frequency) by simulating the stock-out of the best-selling Mars confections products. This provides direct evidence about which products are close substitutes, and how the costs of stock-outs are distributed throughout the supply chain. It also provides exogenous variation in the choice sets of consumers, which helps to identify the discrete-choice model of consumer choice.

In principle, calculating the e ect of product removals is straightforward. In practice, however, there are two challenges in implementing the removals and interpreting the data generated by them. First, there is variation in overall sales at the weekly level, independent of our exogenous removals. Second, although the experimental design is relatively clean, the product mix presented in a machine is not necessarily xed across machines, or within a machine over long periods of time, and we rely on observational data for the control weeks. To mitigate these issues, we report treatment e ects of the product removals after selecting control weeks to address these issues. We provide the details of this procedure in Appendix A.4.

3.4 Results of Product Removals

Our rst exogenous product removal eliminated Snickers from all 66 vending machines involved in the experiment; the second removal eliminated Peanut M&Ms, and the third eliminated both products.³⁸ These products correspond to the top two sellers in the confections category, both at Mark Vend and nationwide.

One of the results of the product removal is that many consumers purchase another product in the vending machine. While many of the alternative brands are owned by Mars, several of them are not. If those other brands have similar (or higher) margins for Mark Vend, substitution may cause the cost of each product removal to be distributed unevenly across the supply chain. Table 5 summarizes the impact of the product removals for Mark

³⁷For example, at some site-experiment pairs, we de ne weeks as Tuesday to Monday, while for others we use Thursday to Wednesday.

³⁸As noted in table 1, both Snickers and Peanut M&Ms are owned by Mars.

Vend. In the absence of any rebate payments, we see the following results. Total vends decrease by 217 units and retailer pro ts decline by \$56.75 when Snickers is removed. When Peanut M&Ms is removed, vends go down by 198 units, but Mark Vend's average margin on all items sold in the machine rises by 0:78 cents, and retailer revenue declines only by \$10.74 (a statistically insigni cant decline). Similarly, in the joint product removal, overall vends decline by roughly 283 units, but Mark Vend's average margin rises by 1:67 cents per unit, so that revenue declines by only \$4:54 (again statistically insigni cant).³⁹

Table 6 examines the impact of the product removals on the upstream rms. Removing Peanut M&Ms decreases Mars' revenue by about \$68:38, compared to Mark Vend's loss of \$10.74; thus roughly 86.4% of the cost of stocking out is born by Mars (reported in the column). In the double removal, because Peanut M&M customers can no longer buy Snickers, and Snickers customers can no longer buy Peanut M&Ms, Mars bears 96:7% of the cost of the stockout. In the Snickers removal, most of the cost appears to be born by the downstream rm; one potential explanation is that among consumers who choose another product, many select another Mars Product (Twix or Peanut M&Ms). We also see the impact of each product removal on the revenues of other manufacturers. Hershey (which owns Reese's Peanut Butter Cups and Hershey's Chocolate Bars) enjoys relatively little substitution in the Snickers removal, in part because Reese's Peanut Butter cups are not available as a substitute. In the double removal, when Peanut Butter Cups are available, Hershey pro ts rise by nearly \$61:43, capturing about half of Mars' losses. We see substitution to the two Nestle products in the Snickers removal, so that Nestle gains \$19:32 as consumers substitute to Butter nger and Raisinets; Nestle's gains are a smaller percentage of Mars' losses in the other two removals.

Direct analysis of the product removals can only account for the marginal cost aspect of the rebate (i.e., the price reduction given by $\)$; one requires a model of restocking in order to account for the threshold aspect, $\overline{\ M}$. By more evenly allocating the costs of stocking out, the rebate should better align the incentives of the upstream and downstream $\$ rms, and lead the retailer to increase his overall service level. Returning to table 5, the right-hand panel reports the retailer's pro $\$ t loss from the product removals after accounting for his rebate payments, assuming he quali es. We see that the rebate reallocates approximately (\$17, \$30, \$50) of the cost of the Snickers, Peanut M&Ms, and joint product removals from the upstream to the downstream $\$ rm. The last column of table 6 shows that after accounting

³⁹Total losses appear smaller in the double-product removal in part because we sum over a smaller sample size of viable machine-treatment weeks (89) for this experiment, compared to the Peanut M&Ms removal (with 115 machine-treatment weeks).

for the rebate contract, the manufacturer bears about 50% of the cost of the Peanut M&Ms removal, 60% of the cost of the joint removal, and 12% of the cost of the Snickers removal.

4 Estimation

4.1 Consumer Choice

In order to consider the optimal product assortment, we need a parametric model of consumer choice that predicts sales for a variety of dierent product assortments. We estimate a mixed (random-coe cients) logit model on our sample of 66 machines (including both experimental and non-experimental periods).⁴⁰

We consider a model of utility in which consumer *i* receives utility from choosing product *j* in market *t* of:

$$U_{ijt} = j_t + ij_t + "_{ijt}. \tag{4}$$

The parameter jt is a product-speci c intercept that captures the mean utility of product j in market t, and jt captures individual-speci c correlation in tastes for products. Each consumer has an outside option $u_{ijt} = u_{i0t}$

 $_t$. The rst allows for 15,256 xed e ects, at the level of a machine-service visit, while the second allows for 2,710 xed e ects, at the level of a machine-choice set (i.e., we combine machine-service visit `markets' for which the choice set does not change). We report the log-likelihood, Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC) for each speci cation. We use BIC to select the speci cation with 2,710 $_t$ xed e ects. Our simulated MLE parameters tend to be very precisely estimated, because we observe 2.96 million sales.

Parametric identi cation of d_j and parameters is straightforward. The d_j parameters would be identified from average sales levels in even a single market after we normalize the jutility of the outside gooutside (s38 tnm(Info4055.imeormat92.96)]TJ 03Ima.928 Td [(mil7.633.94)]

The retailer's problem is:

where $^{R}(a;e)$ is the variable pro t of the retailer absent any rebate payment, $^{M}(a;e)$ is the variable pro t of the dominant manufacturer M, and c(e) represents the cost of retailer e ort.

The retailer's assortment decision involves simple discrete comparisons across a nite number of choices. We explain the set of potential assortments that we analyze in section 4.2.3. For each potential choice of assortment, we calculate the retailer's optimal choice of e ort.

4.2.1 Retail E ort Choice: Dynamic Model of Re-stocking

We believe that Mark Vend's e ort decision is operationalized as follows. At the beginning of each quarter, MarkVend decides on an (enterprise-wide) policy to restock after *e* likely consumers have arrived at all of his vending machines. He then translates this policy into a restocking schedule for each individual vending machine (e.g., every Tuesday, every 10 days, every other day, etc.) based on knowledge of a machine-specie c arrival rate. Once the schedule for the quarter is set, he breaks up the schedule into individual service routes, and assigns routes to drivers and trucks. In order to reduce the number of consumer arrivals between service visits, MarkVend must hire additional trucks and drivers, which increases his costs. An implication of this setup is that MarkVend commits to a restocking policy for an entire quarter. This means that if sales are below expectations (i.e., if he repeatedly draw from the left-tail of the consumer arrival distribution), MarkVend does not adjust his stocking policy until the next quarter.⁴⁷

In our application, we consider the speciec case in which the retailer chooses the restocking frequency. We model the retailer's choice of e ort, e, using an approach similar to Rust

⁴⁶Mars' AUD rebate contract is evaluated quarterly on the basis of MarkVend's entire enterprise, which includes 728 snack vending machines.

⁴⁷Within a quarter, it appears as the most machines are on an extremely predictable xed schedule, and there is no evidence that the schedule is adjusted in either direction towards the end of each quarter. This is consistent with a model of e ort in which the frequency of service is set in response to the payo function, but the schedule is not set dynamically within a quarter as a function of the distance from the threshold. As Mark Vend does not observe sales, except at the time of a service visit, this makes a lot of sense. He doesn't have new information by which to dynamically adjust a service schedule across days.

(1987), but `in reverse.' Rather than assuming that observed retailer wait times are optimal and using Rust's model to estimate the cost of re-stocking, we use an outside estimate of the cost of re-stocking based on wage data from the vending operator, and use the model to

This also enables us to evaluate pro ts under alternative stocking policies x^{0} , or policies that arise under counterfactual market structures. For example, in order to understand the incentives of a vertically-integrated rm, M+R, we can replace u(x) with $(u^{R}(x)+u^{M}(x))$, which incorporates the pro ts of the dominant upstream manufacturer. Likewise, we can consider the industry-optimal policy by replacing u(x) with $(u^{R}(x)+u^{M}(x)+u^{H}(x)+u^{N}(x))$.

To nd the optimal policy we iterate between (9) and the policy improvement step:

$$X = \min X : u(X) \quad FC + \quad V(0;X) \qquad P(X^{0};X) V(X^{0};X) : \tag{10}$$

The xed point (x; V(x;x)) maximizes the long-run average prot of the agent (x)V(x;x) where P = is the ergodic distribution corresponding to the post-decision transition matrix. These long-run prots will become the basis on which we compare contracts and product assortment choices.

4.2.2 Retail E ort Choice: Empirical Implementation

In order to compute the dynamic restocking model, we construct a 'representative vending machine' via the following procedure. We de ne a 'full machine' as one that contains a set of the 29 most commonly-stocked products, which we report in table 8, and we use actual machine capacities for each product.⁵⁰ Beginning with a full machine, we simulate consumer arrivals one at a time and allow consumers to choose products in accordance with the mixed logit choice probabilities $s_{jt}(\cdot; \cdot; a_t)$ (including an outside option of no-purchase). After each consumer choice, we update the inventories of each product and adjust the set of available products a_t if a product has stocked out. When products stock out, consumers substitute to other products, including the no-purchase option. We continue to simulate consumer arrivals until the vending machine is empty. We average over 100,000 simulated chains to construct the expected protes after x consumers have arrived, and to a smooth Chebyshev polynomial to the protes of each agent $\mathcal{U}^R(x)_t \mathcal{U}^M(x)_t \mathcal{U}^H(x)_t \mathcal{U}^C(x)_t$.

The state variable of our dynamic programming problem, X_t , is the number of potential consumers who have arrived since our `representative vending machine' was last restocked. The exogenous state transition matrix $P(X_{t+1} \mid X_t / X_t) \mid P(\mid X_t)$ is the incremental number of potential consumers who arrive to the representative vending machine each business day.

⁵⁰These capacities are nearly uniform across machines, and are: 15-18 units for each confection product, 11-12 units for each salty snack product, and around 15 units for each cookie/other product.

 $^{^{51}}$ The t of the 10th order Chebyshev polynomial is in excess of R^2 0.99. It is generally well behaved except at the very edges of the state space, but these are far from our optimal policies.

We assume that the arrival rate has a discrete distribution.⁵² In a separate stage, we use 28 of our 66 experimental machines to form a non-parametric estimate of P(x). These 28 machines have an average daily sales volume of 15:1 units and a standard deviation of 2:0 units.⁵³ For each service-visit observation at each of these machines, we use the number of estimated consumer arrivals since the last service visit, and divide this by the number of elapsed business days since the last visit to compute the number of daily consumer arrivals, x_t .⁵⁴ E ort policies are not particularly sensitive to the specilication of the arrival process.⁵⁵

We choose a daily discount factor = 0.999863, which corresponds to a 5% annual interest rate. We assume a xed cost of a restocking visit, FC = \$10, which approximates the per-machine restocking cost using the driver's wage and average number of machines serviced per day. As a robustness test, we also consider FC = f5;15g, which generate qualitatively similar predictions. In theory, one should able to estimate FC directly o the data using the technique of Hotz and Miller (1993). However, our retailer sets a level of service that is too high to rationalize with any optimal stocking behavior, often re Iling a day before any products have stocked-out. This is helpful as an experimental control, but makes identifying FC from data impossible.

In order to speed up computation, we normalize our state space when solving the dynamic programming problem. Instead of working with the number of consumers to arrive at

⁵²This mimics Rust (1987) who estimates a discrete distribution of weekly incremental mileage.

⁵³The machines in this group have higher than average sales volumes, but are not the largest machines. We chose this group for our exercise because we think it is the most important set of machines for determining the retailer's re-stocking decision. For additional detail, please see Appendix A.5.

⁵⁴Note that the data report average daily sales, rather than consumer arrivals (i.e., there are no cameras on the vending machines). As in the consumer choice model, the relationship between observed sales and consumer arrivals depends on availability. If a machine is empty, no sales will occur, regardless of the consumer arrival rate. The consumer choice model adjusts for this by allowing substitution to remaining products (including the outside good) when a machine is not fully stocked. Our estimate of consumer arrivals uses the same adjustment.

⁵⁵Doubling or tripling the rate at which consumers arrive has very little e ect on the optimal e ort policy, because policies are de ned in terms of the cumulative number of consumer arrivals (rather than days, for example). In robustness tests, we assume that the rm can make decisions consumer-by-consumer, or only every four `days.' With appropriate scaling of the discount factor , the optimal policies change by only 2-3 units.

⁵⁶In conversations with the retailer about his service schedule, he provided two explanations of this fact. First, he suspected that he was over-servicing, and reduced service levels after our eld experiment. Second, he explained that high service levels are important to obtaining long-term (3-5 year) exclusive service contracts with locations. Our speci c experimental locations almost certainly do not re ect a company-wide servicing policy. Speci cally, these are high-end o ce buildings with high service expectations. Public

the vending machine, we work with the number of consumers who would have likely made a purchase at a hypothetical `full' vending machine. This saves us from simulating large numbers of consumers who always choose the outside good, independent of product assortment. We thus label our state-space as `likely' consumer arrivals instead of `potential' consumer arrivals from this point forward.⁵⁷

By simulating from our consumer choice model in section 4.1, we can compute the payo s to each agent from any assortment a and any e ort level e using equation (9). For the retailer, with e ort policy e:

$$R(a;e) = (P(e)) (I P(e))^{-1} \dot{u}^{R}(x;a);$$
 (11)

and represents the net present value of the long-run average (in nite horizon) pro $\,$ ts of a single representative vending machine under assortment a

payo s at (a;e) for each agent for 15 possible assortments. Each of the 15 possible assortments includes Mark Vend's ve most commonly-stocked chocolate confections products: four Mars products (Snickers, Peanut M&Ms, Twix, and Plain M&Ms), and Nestle's Raisinets. The retailer is always worse o if he replaces any of these ve products with a di erent product. We then allow the retailer to choose any pair of products for the nal two slots in the confections category from a set of six products. The six products we consider include two Mars products (Milky Way and Three Musketeers), two Hershey products (Reese's Peanut Butter Cup and PayDay), and two Nestle products (Butter nger and Crunch). Although we compute the full model for all 15 possible assortments, only three end up being pay-o relevant: (M;M) { 3 Musketeers and MilkyWay, (H;M) } 3 Musketeers and Reese's Peanut Butter Cups, and (H;H) } Reese's Peanut Butter Cup and PayDay.

Finally, Mark Vend's assortment decision is discrete (either a product is on the shelf of the vending machine or it isn't), and our e ort decision is discrete (we are restricted to restocking after an integer number of likely consumer arrivals). Thus, we can, and do,

order to convert consumer surplus into dollars, we perform a calibration exercise in which we assume that the median own-price elasticity is 2. We view this as a relatively inelastic

rebate at the observed ($^{M}(H;M) = 1;882$) exceeds the gains to Mars ($^{M} = 1;657$). Thus, Mars pays more to partially foreclose Hershey than it expects to gain from partial foreclosure. This cannot be an equilibrium outcome.

The second column of the second pane of table 9 starts from (H;M) and considers a move to (M;M). Now Reese's Peanut Butter Cup is replaced by MilkyWay and Hershey is fully foreclosed. Again, the retailer gives up some pro t absent the rebate payment ($^R = 308$), the dominant rm gains ($^M = 1;338$), and bilateral surplus increases ($^M + ^R = 1;030$). However, the gain in bilateral surplus is smaller than the losses to the rival ($^H = 1;030$).

would be too generous. Likewise, if Mars believes that, absent the rebate, the retailer would have stocked (H;M), the rebate would not be generous enough to induce the retailer to switch from (H;M) ! (M;M).

5.2 Role of the Threshold

These results are meant to parallel those in section 2.3. We explore how the rebate threshold $^{-M}$ a ects the retailer's choice of assortment and e ort, assuming that wholesale prices and the rebate discount—are—xed at their observed values. Figure 2 plots two curves. Each curve represents the pro—ts of the retailer after receiving the rebate (i.e., $^{R}(a;e) + ^{M}(a;e)$). The horizontal axis reports revenue of the dominant—rm, M . The left curve represents the retailer's pro—ts with an (H;M) assortment. The right curve represents the retailer's pro—ts with a (M;M) assortment. As we move across each curve from left to right, the retailer's

until he reaches $^{-M} = 13$;

e ort levels.⁶⁷ Under an (M;M) assortment, switching from the no-rebate retailer e ort policy (e^{NR}) to the vertically-integrated optimal e ort policy (e^{VI}) increases the restocking frequency by 7.95%. We use the e^{NR} e ort level rather than the e^{R} e ort level as our baseline in order to capture the maximum potential e ciency gains from the rebate contract.⁶⁸ Higher e ort is costly to the retailer (M = 55) and bene cial to Mars (M = 128), leading to a net gain in producer surplus (PS = 63) once we include competing manufacturers. Most

socially-optimal e ort level, e^{SOC}

The right panel of table 14 conducts the same exercise, but assumes that the retailer would choose the (H;M) assortment in the absence of Mars' rebate. Under this scenario, the rebate is much too generous and could be reduced by 38.18% to 44.79% while still foreclosing Hershey. Relatedly, holding xed, Hershey would need to set a negative wholesale price (i.e., pay the retailer to sell its products). This highlights the fact that the rebate terms are only sensible as a device to make the retailer switch from (H;H)! (M;M).

5.5 Comparison to Uniform Wholesale Pricing by Mars

In lieu of an AUD, Mars could charge a lower wholesale price without conditioning on a threshold $^{-M}$. Table 15 presents results for a uniform wholesale price by Mars. We hold xed the wholesale prices of Hershey and Nestle $(w_h; w_n)$, and compute a new optimal wholesale price for M, w_m^l . The resulting set of wholesale prices $(w_m^l; w_h; w_n)$ does not constitute an equilibrium (because $(w_h; w_n)$ are not allowed to adjust). Therefore, the exercise is meant as tool to understand how the AUD reduces the price of foreclosure to the dominant rm, rather than re ecting what would happen to equilibrium prices in the absence of an AUD by Mars.

The main result is that Mars' wholesale price is lower than the post-discount wholesale price under the AUD. E ectively, Mars pays more for foreclosure without the threshold. We quantify exactly how much more by comparing Mars' uniform wholesale price to an AUD that forecloses under two di erent e ort levels: e^R and e^{VI} . Mars' pro t (after rebates), (1) M , falls from \$11,005 to \$10,094, for a loss of \$911. The retailer's pro t increases by a similar amount (\$921, or \$39,103 - \$38,182). The gains to the retailer are slightly larger if the threshold under the AUD had been used to implement the vertically-integrated e ort level.

We plot the best response of Mars to the observed $(w_h; w_n)$ prices in gure 4. We do not consider an equilibrium in which all three upstream rms simultaneously set wholesale prices $(w_m; w_h; w_n)$. The challenge for modeling this is that no Nash equilibrium exists in pure strategies because the retailer's assortment decision is discrete; only a mixed-strategy Nash equilibrium exists.⁷¹

⁷⁰It should also be clear that adjusting the baseline from (H;H) to (H;M) means that the current rebate violates Mars's IR constraint (B2) as noted in table 9.

⁷¹The non-existence of pure-strategy equilibria is well documented in the theoretical literature (e.g., see recent work by Jeon and Menicucci (2012)), and derives from the fact that agents' best-response functions are discontinuous, and need not cross. The mixed-strategy Nash equilibrium of the uniform wholesale pricing

5.6 Implications for Mergers

Vending is one of many industries for which retail prices are often xed across similar products and under di erent vertical arrangements. Indeed, there are many industries for which the primary strategic variable is not retail price, but rather a slotting fee or other transfer payment between vertically-separated rms. Thus, our ability to evaluate the impact of a potential upstream merger may turn on how the merger a ects payments between rms in the vertical channel. We consider the impact of three potential mergers (Mars-Hershey, Mars-Nestle, and Hershey-Nestle) on the AUD terms o ered to the retailer by Mars. Given the degree of concentration in the confections industry, antitrust authorities would likely investigate proposed mergers, especially mergers involving Mars.⁷²

Table 16 measures how competing manufacturers might respond to an upstream merger. The rst column duplicates the second column of table 14 as a baseline. In the second column, we examine a potential Mars-Hershey merger. We assume that after the merger, the Hershey product (Reeses Peanut Butter Cup) is priced at the Mars wholesale price and included in Mars' rebate contract. The merged (Mars-Hershey) rm is now happy for consumers to substitute to Reese's Peanut Butter Cups, and the AUD is able to achieve the industry-optimal (and socially-optimal) product assortment of (H,M). The merged rm faces competition from Nestle (Nestle Crunch and Butter nger), which charges lower wholesale prices but sells less-popular products. In the absence of an AUD, the retailer maximizes his protection to by stocking the two Nestle products, but the AUD induces the retailer to choose an (H,M) assortment and an e^{VI} or the policy (evaluated at the observed discount and wholesale prices). Although not reported in table 16, the AUD also maximizes social surplus by inducing the socially-optimal (H;M) assortment and a high e ort level.

We consider the possibility that Nestle may be able to cut its price in order to avoid having Butter nger and Nestle Crunch foreclosed. Following the same exercise that was performed in table 14, we nd that Nestle would need to charge a negative wholesale price to the retailer in order to induce him to stock the less-popular Nestle products (similar to condition (A3)). Knowing that the Nestle productss provide weak discipline for the merged Mars-Hershey rm, we next examine whether the merged Mars-Hershey rm can reduce the

⁷²For a related analysis of diversion ratios in this market, see Conlon and Mortimer (2013b).

⁷³We assume that the AUD retains at the pre-existing level, and sets $\overline{M} = M(e^{VI}(H;M))$ to induce the vertically-integrated optimal level of e ort.

⁷⁴We use Nestle's observed wholesale price when computing changes in pro ts and producer surplus.

⁷⁵Table 16 reports changes in variable pro t for each agent, but not levels. For the full details of post-merger pro ts (or revenues for manufacturers) at all (a;e), please see Appendix A.9.

⁷⁶Producer surplus and consumer utility for each potential merger are also reported in Appendix A.9.

generosity of its rebate. Pre-merger, we found that the rebate was 3.53% too generous; after the merger it is 42.3% too generous. This implies that the market is unlikely to obtain the post-merger outcome in which the retailer stocks the socially-optimal assortment, because the discipline imposed by Nestle's products is likely too weak to keep the current AUD terms in force.

We perform a similar exercise in the third column, in which we allow Mars and Nestle to merge. The main di erence now is that the merged rm internalizes the pro ts of Nestle's Raisinets, and is able to include the pro t from Raisinets in the rebate. This again provides incentives for the merged rm to reduce the generosity of the rebate (by 12:67%).⁷⁷ Finally, we examine a Hershey-Nestle merger in the nal column. Giving Hershey access to the pro ts of Raisinets does very little, because Raisinets is not in danger of being foreclosed. This exercise closely resembles our baseline (No Merger) scenario.

Throughout the paper, we report the variable pro ts for the retailer; it is likely that his overall operating pro ts, after accounting for administrative and overhead costs, are substan-

Identi	cation of both	n the consume	r choice and	retailer-e	ort models ben	e ts from exogenous

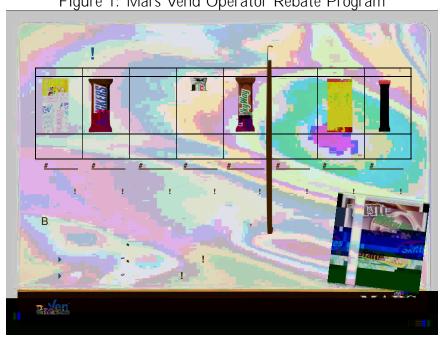

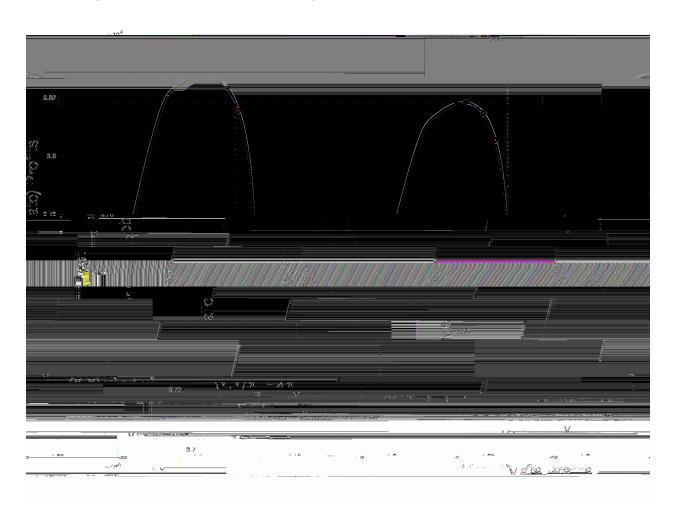

Figure 1: Mars Vend Operator Rebate Program

 $Notes: From `2010 Vend Program' materials, dated December 21, 2009; last accessed on February 2, 2015 at \\ http://vistar.com/KansasCity/Documents/Mars%202010%20Operatopr%20rebate%20program.pdf.$

Notes: Figure reports retailer variable pro-t under two assortment choices ((H,M) on the left and (M,M) on the right), against revenues of Mars products. For a threshold $^{-M}$ 11,912 (noted by the vertical dashed line), the retailer prefers to switch his assortment from (H,M) to (M,M). Three points are marked on each curve. The left-most point on each curve represents an e^R e ort policy for the relevant assortment; the point to the right of e^R represents an e^{VI} e ort policy, and the right-most point represents an e^{SOC} e ort policy.

Figure 3: Pro ts Per Consumer as a Function of the Restocking Policy

Notes: Each curve reports the prots of the retailer, Mars, Hershey and Nestle as a function of the retailer's restocking policy, using the product assortment in which the retailer stocks 3 Musketeers (Mars) and Reese's Peanut Butter Cups (Hershey) in the nal two slots. Specifically, the vertical axes report variable prot per consumer for each of the four firms, and the horizontal axes report the number of expected sales between restocking visits.

Figure 4: Mars Pro ts as a Function of Price (Linear Pricing)

Notes: Reports Mars' pro t at di erent linear wholesale prices, holding xed the wholesale prices of Hershey and Nestle. The discontinuities re ect prices at which the retailer drops a Mars product from its assortment.

Table 1: Comparison of National Availability and Shares with Mark Vend

		National:		Mark Vend:		Experimental:		
Manu-			Avail-		Avail-		Avail-	
facturer	Product	Rank	ability	Share	ability	Share	ability	Share

Mars	Milky Way	13	39	1.7	33	2.8	18	1.5
Nestle	Raisinets	> 45	N/R	N/R	45	4.0	81	8.7

Notes: National Rank, Availability and Share refers to total US sales for the 12 weeks ending May 14, 2000, reported by Management Science Associates, Inc., at http://www.allaboutvending.com/studies/study2.htm, accessed on June 18, 2014. National gures are not reported for Raisinets because they are outside of the 45 top-ranked products. By manufacturer, the national shares of the top 45 products (from the same source) are: Mars 52.0%, and Hershey 20.5%. For Mark Vend, shares are: Mars 73.6%, and Hershey 15.0% and for our experimental sample Mars 78.3% and Hershey 13.1% (calculations by authors).

Table 2: Assortment Response to Changes in the Threshold

	Achieved	Total	Mars
	Threshold %	Vends	Share
2007q1	109.16	1000.00	20.20
2007q2	106.29	1087.45	19.77
2007q3	100.81	1008.57	20.94
2007q4	105.23	1092.49	19.97
2008q1	106.27	1103.42	19.45
2008q2	97.20	1057.32	19.77
2008q3	91.88	1014.13	19.14
2008q4	87.02	1048.26	18.11
2009q1	87.03	1058.54	17.65

Notes: Achieved threshold % reports the ratio of total Mars sales relative to Mars sales in the same quarter one year prior. For quarters 2007q1-2008q1 we believe the target to be 100% with a bonus payment at 105%. For quarters 2008q3-2009q1 we believe the threshold was reduced to 90%.

Notes: The top pane reports revenues under three assortments using an e^R e ort policy for each one. The second pane reports changes in variable pro t from moving from one assortment to another, as indicated. Rebate ranges in the third pane re ect the IR and IC constraints of the retailer and Mars. Standard errors are computed according to the procedure in Appendix A.6. The reported 'Observed' rebate uses the observed discount in the calculation of the rebate payment. CS assumes a demand elasticity of e^R

Table 10: Critical Thresholds and Foreclosure at Observed

Notes: Table compares the welfare impacts of an exclusive Mars stocking policy under alternative ownership structures. This assumes threshold is set at the vertically-integrated e ort level.

Appendix

A.1: Proof of Theorems

Proof of Theorem 1:

Note: We can relate our (linear) delta operators to one another via:

= M + H

(A3) provides that ${}^{I}(M;M) > {}^{I}(H;H)$. (B3) provides ${}^{I}(H;M) > {}^{I}(H;H)$ and (C4) provides that ${}^{I}(H;M) > {}^{I}(M;M) > {}^{I}(M;M) > {}^{I}(H;H)$.

Absent transfers, if R selects the assortment then R(H;H) > R(H;M) > R(M;M) implies that the equilibrium assortment will be (H;H). If we temporarily ignore (H;M) then (A1)-(A3) say that in a choice between M;M and H;H it is possible to design a transfer H;H which leads to assortment H;H which leads to assort H;H which leads to assort H;H which leads to assort H;H which leads to assortment H;H which leads to assort H;H which leads H;H which H;H which leads H;H which leads H;H which leads H;H which

A.2: Alternative Contracts

This section compares the AUD contract to other contractual forms; it is meant to be expositional and does not present new theoretical results.

Quantity Discount

A discount d, can be mapped into (a share of M's variable pro t margin). However the discount no longer applies to all q_m , only those units in excess of the threshold, so that $(\overline{M}) = \max_{m \in \mathbb{N}} 0$. This implies T (\overline{M}) M, so that as the threshold increases M is limited in how much surplus he can transfer to R, assuming that the post-discount wholesale price is nonnegative. In the limiting case, the threshold binds exactly and M cannot o er R any surplus. This makes the discount, rather than the threshold, the primary tool for incentivizing e ort. (Recall that for the AUD, $\overline{e} = e^R$ implies that M can directly set the retailer's e ort). This means that high e ort levels, $e > e^R$, will be more expensive to the dominant R under the quantity discount than under the AUD. In fact, the vertically-integrated level of e ort is only achievable through the 'sell out' discount, where R is such that R earns no prot on the marginal unit, and some R signi cantly less than the vertically-integrated quantity.

Quantity Forcing Contract

The quantity forcing (QF) contract is similar to a special case of the AUD contract. Specify a conventional AUD (w_m ; d; \overline{q}_m) as:

One can increase the wholesale price v_m by one unit, and the generosity of the rebate (t) by one unit. Continuing with this procedure, the retailer pro ts when the threshold is met. For any q_m \Rightarrow as:

One can also construct a two-part tari (2PT), described by two terms: a share of M's revenue and a xed transfer T from $R \mid M$. The retailer chooses between the 2PT contract and the standard wholesale price contract.

We de ne

In the case where the rebate is paid, we can express the retailer's problem as:

$$e_1 = \arg \max_{e} \ ^R(e) \ c(e) + \ ^M(e) \ \text{s.t.} \ ^M(e)$$

The solution to the constrained problem is given by:

$$e_1 = \max f e^R$$
; $\overline{e}g$ where \overline{e} solves $\overline{M}(\overline{e}) = \overline{M}$

If the rebate is not paid then:

$$e_0 = e^{NR} = \arg\max_e R(e) \quad c(e)$$

The retailer's IC constraint:

$$R(e_1)$$
 $c(e_1) + M(e_1)$ $R(e_0)$ $c(e_0)$ (IC)

and the dominant rm M's IR constraint:

(1)
$$M(e_1)$$
 $M(e_0)$ (IRM)

When we consider the sum of (IC) and (IRM) it is clear that a rebate which induces e ort level e_1 must increase bilateral surplus relative to e_0 :

$$^{R}(e_{1})$$
 $c(e_{1}) + ^{M}(e_{1})$ $^{R}(e_{0})$ $c(e_{0}) + ^{M}(e_{0})$

This provides an upper bound on the e ort that can be induced by the rebate contract.

A.4: Computing Treatment E ects

One goal of the exogenous product removals is to determine how product-level sales respond to changes in availability. Let $q_{j\,t}$ denote the sales of productj in machine-week t, superscript 1 denote sales when a focal product(s) is removed, and superscript 0 denote sales when a focal product(s) is available. Let the set of available products be A, and let F be the set of products we remove. Thus, $Q_t^1 = \int_{j \ge A} q_{j\,t}^1$ and $Q_s^0 = \int_{j \ge F} q_{j\,s}^0$ are the overall sales during treatment week t, and control week s respectively, and $q_{f\,s}^0 = \int_{j \ge F} q_{j\,s}^0$ is the sales of the removed products during control week s. Our goal is to compute $q_{j\,t} = q_{j\,t}^1$ $E[q_{j\,t}^0]$, the treatment s ect of removing products(s) s on the sales of products.

There are two challenges in implementing the removals and interpreting the data generated by them. The rst challenge is that there is a large amount of variation in overall sales at the weekly level, independent of our exogenous removals. For example, a law rm may have a large

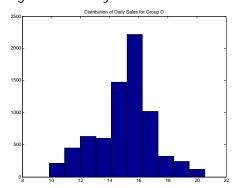

case going to trial	in a given month,	and vend levels	will increase at the	rm during that period.

Table 17: Summary of Sales and Revenues for Four Clusters of Machines

	Group Size	Vends/Visit		Revenu	e/Visit	Avg Sales/Day	
		Mean	S.D.	Mean	S.D.	Mean	S.D.
Α	4	39.0	26.1	28.3	18.7	5.8	1.4
В	7	88.9	39.5	70.6	33.4	24.9	3.0
C	27	56.9	31.5	41.5	23.2	9.2	1.4
D	28	71.6	33.8	54.3	26.8	15.1	2.0

Notes: The 66 machines in our analyses are divided into four groups of machines based on the arrival rate and the amount of revenue collected at a service visit, using a k-means clustering algorithm. Our counterfactual analyses are based on cluster D.

Figure 5: Histogram of Daily Sales for Machines in Group D

Notes: The 28 machines in group D form the basis for our counterfactual exercises. Means and standard deviations for all machine groups are reported in table 17.

- 5. Fit a Chebyshev Polynomial (order 10) to the average of each computed sequence of pro ts: $u^{R}(x;a)^{h}(x;a)^{h}$, etc.

$$(a;ej^{h}) = (P(e)) (I P(e))^{-1} O(x;aj^{h}).$$

- 7. Use $(a;ej^{\Lambda b})$ to calculate the optimal policies for di erent groups of agents $(e^{NR};e^{R};e^{VI};e^{SOC})$ for every a.
- 8. Compute all of the pro t di erences R; M; H for Tables 9-15.
- 9. Repeat 1000 times and report the standard deviations.

In this procedure there are two sources of variation. The rst is the variation introduced by the uncertainty in the MLE estimates of the demand parameters (as reported in Table 7). The second is the simulation variance introduced from our simulation procedure, because we use the average over 100,000 chains this is designed to be at most \$2.

A.7: Consumer Surplus and Welfare Calculations

Our calculation of the expected consumer surplus of a particular assortment and e ort policy (a;e) parallels our calculation of retailer pro ts. We simulate consumer arrivals over many chains, and compute the set of available products as a function of the initial assortmenta and the number of consumers to arrive since the previous restocking visitx which we write a(x). For each assortment a(x) that a consumer faces, we can compute the logit inclusive value and average over our simulations, to obtain an estimate at each x:

$$CS(a;xj) = \frac{1}{NS} \sum_{s=1}^{NS} \log^{@} \times \exp[j + ij()]^{A}$$

The exogenous arrival rate, $f(x^0/x)$, denotes the expected daily number of consumer arrivals (from x cumulative likely consumers today to x^0 cumulative likely consumers tomorrow). Using this arrival rate and a policy x(e), we obtain the post-decision transition rule P(x(e)) and evaluate the ergodic distribution of consumer surplus under policy e:

$$CS(a;e) = (I P(x(e)))^{-1}CS(a;xj)$$

The remaining challenge is that CS (a;e) relates to arbitrary units of consumer utility, rather than dollars. Recall our utility speci cation from (4), with $= [\ ; \]$:

$$u_{ijt}(\)=\ _{j}+\ _{p_{j}t}+\ _{t}+\ _{l}$$

Without observable, within-product variation in price, $p_{jt} = p_j$, and is not separately identi ed from the product xed-e ect $_j$. If were identi ed, then we could simply write $CS(a;e) = {}^{1}CS$ (a;e). Instead, we can calibrate given an own price elasticity:

$$_{j;t} \ = \ \frac{p_{jt}}{s_{jt}} \quad \frac{@_{1}}{@_{1}p_{i}} = \frac{p_{jt}}{s_{jt}} \quad Z \quad \frac{@_{1}p_{i}}{@_{1}p_{i}} f\left(\begin{array}{c} ij \end{array}\right) d \quad _{i} = \quad \frac{p_{jt}}{s_{jt}} \quad Z \quad _{i;t} \left(\begin{array}{c} z \\ \end{array}\right) \left(\begin{array}{c$$

The term $_{j;t}$ does not depend directly on once we have controlled for the xed e ect d_j . Thus, we can calibrate own-price elasticities. As is conventional in the literature, we work with the median own-price elasticity, $^-$ () = median $_j$ ($_{j;t}$ ()), and recover as = $_j$ can the direction of the xed e ect d_j . Thus, we can calibrate own-price elasticity, $^-$ () = median $_j$ ($_{j;t}$ ()), and recover as = $_j$ can the xed e ect d_j . Thus, we can calibrate own-price elasticity $_j$ () = median $_j$ ($_{j;t}$ ()), and recover as = $_j$ can the xed e ect $_j$. Thus, we

Notes: Reports potential gains realized when e ort is chosen to maximize combined retailer-consumer surplus, under di erent assumptions for median own-price elasticity when calculating consumer surplus.

in our base scenario.

In Table 21, we calculate the optimal assortment decision of a joint Retailer-Consumer pair. We not that the assortment choice depends on how much weight the retailer places on consumer surplus, or how elastic consumers are. Assuming the retailer places full weight on consumer surplus, at a median own price elasticity of = 2 the retailer is more or less indi erent between the (H;M) assortment and the (H;H) assortment. As consumers become more elastic, the retailer-consumer pair prefers (H;H), and as they become less elastic the retailer-consumer pair prefers the consumer-optimal assortment (H;M).

We combine foreclosure and e ciency e ects where we treat the retailer-consumer as a jointly maximizing pair in Table 22. When consumers are su ciently inelastic, and the retailer accounts for consumer utility when choosing the assortment, he selects $\mathcal{H}(\mathcal{M})$. In this world, any rebate which induces a switch to $(\mathcal{M};\mathcal{M})$ decreased both producer and consumer surplus. As consumers

Notes: Pro t numbers represent the long-run expected pro t from a 'representative' machine. Rebate payments are assumed to only be paid under an (M;M) assortment; rebate payments under other assortments are reported in light typeface, but are assumed to not be paid to the retailer. The retailer's optimal assortment under each e ort policy is reported in boldface type. The socially-optimal assortment is (H;M); we denote this with boldface type for the PS and CS columns.
